**Abstract:** Determination of double-K fracture parameter using both analytical and weight function method is carried out in present research. In calculating the cohesive fracture toughness, two situations are divided at critical load. Wedge-splitting tests with ten temperatures varying from 20°C to 600°C are implemented. The complete load-crack opening displacement curves are obtained from which the initial and critical fracture toughness could be calculated experimentally. The validation of double-K fracture model to the post-fire concrete specimens is proved. Meanwhile the weight function method agrees well with the analytical method.

**Keywords:** double-K fracture parameter, analytical method, weight function method, post-fire concrete

## 1. Introduction

It was established that linear elastic fracture mechanics could be only applicable to large-mass concrete structures and could not be applicable to medium and small-scale concrete structures. Since late 1970s, many nonlinear fracture models have been proposed by various groups of researchers to study the behavior of crack propagation in quasi-brittle materials like concrete [1-6].

Experimental results show that the fracture process of concrete structures undergoes three main stages: (i) crack initiation, (ii) stable crack propagation, and (iii) unstable fracture. Accordingly, the double-K fracture criterion initially introduced by Xu and Reinhardt [6] shows the crack initiation, crack propagation and failure during a fracture process until the maximum load is reached. And the two size-independent parameters, initial cracking toughness,  $K_I^{ini}$  and unstable fracture toughness,  $K_I^{un}$  can be used to study the crack propagation of concrete.

In order to determine the double-K fracture parameters analytically [7, 8] the value of cohesion toughness,  $K_I^c$  due to cohesive stress distribution in the fictitious fracture zone is computed using method proposed by Jenq and Shah [9]. In this method, the determination of  $K_I^c$  is done using a special numerical technique because of existence of singularity problem at the integral boundary. Under such circumstances, the use of universal form of weight function will provide a closed form expression for determining the value of  $K_I^c$ . And it has proven its accuracy in determining the double-K fracture parameter compared to analytical method [10].

The influences of geometrical parameter [11], specimen geometry [12, 13] and size-effect [7, 8, and 14] on fracture toughness were studied by various researchers. It was found that the influence of  $a_0/D$  ratio and shape of test specimen are relatively less than the size- effect on the values of fracture parameters.

The influence of temperature on the fracture parameters was also considered by several researchers, but mainly on the fracture energy and material brittleness [15-19], relatively fewer discussion on the fracture toughness [20-21].s Considering there exist many structures subjected to fire or high temperatures, the influence of temperature on the fracture properties needs further studied.

The present paper is aimed at to determine the residual fracture toughness of wedge splitting specimens subjected to high temperatures and prove the validation of double-K fracture model to the post-fire concrete. The wedge-splitting experiments of totally ten temperatures varying from 20°C to 600°C and the specimens size 230×200×200 mm with initial-notch depth ratios 0.4 are implemented. Both analytical and weight function methods are used to calculate the residual fracture toughness parameters. Comparison between the two methods and to experimental results is carried out respectively. From the calculated values of double-K fracture parameters using experimental results the nondimensional parameter, brittleness of concrete may be conceived. Hence, the paper is structured to present the following: (i) details of softening traction-separation law of post-fire concrete, (ii) determination of double-K fracture parameters using existing analytical method, (iii) implementation of weight function method, and (v) experimental validation and comparison of results.

## 2. Softening traction-separation law of post-fire concrete

The softening traction-separation law is a prior to determine the double-K fracture parameters, at room temperature, many expressions have been proposed based on direct tensile tests [22-26]. Based on numerical studies, simplified bilinear expressions for the softening traction-separation law (illustrated in Fig.1) were suggested by Petersson in 1981[22], Hilsdorft and Brameshuber in 1991 [25], and Phillips and Zhang in 1993 [26]. The area under the softening curve was defined as the fracture energy  $G_F$  by Hillerborg et al in 1976 [1]. Therefore, one could get the following equation:

$$G_F = \frac{1}{2}(f_t w_s + \sigma_s w_0) \quad (1)$$

As a consequence, a general form of the simplified bilinear expression of the softening traction-separation law is given as follows:

$$\begin{cases} \sigma = f_t - (f_t - \sigma_s)w/w_0 & 0 \leq w \leq w_s \\ \sigma = \sigma_s (w_0 - w)/(w_0 - w_s) & w_s \leq w \leq w_0 \\ \sigma = 0 & w \geq w_0 \end{cases} \quad (2)$$

Fig. 1. The bilinear softening traction-separation law

Different values of the break point  $(\sigma_s, w_s)$  and the crack width  $w_0$  at stress-free point were used for the expression proposed by different researchers. In present work, the bilinear softening function of concrete proposed by Petersson is used for post-fire specimens:

$$\begin{cases} \sigma_s = f_t / 3 \\ w_s = 0.8G_F / f_t \\ w_0 = 3.6G_F / f_t \end{cases} \quad (3)$$

## 3. Analytical determination of cohesive fracture toughness

### 3.1 Effective crack extension length and residual Young's modulus

The linear asymptotic superposition assumption is considered in the analytical method presented by Xu and Reinhardt [7, 8] to introduce the concept of linear elastic fracture mechanics for calculating the double-K fracture parameters. Detailed explanation of the above assumption can be found elsewhere [7].

Based on this assumption, the value of the equivalent-elastic crack length for WS specimen is expressed as:

$$a = (h + h_0) \left\{ 1 - \left( \frac{13.18}{E \cdot b \cdot c + 9.16} \right)^{1/2} \right\} - h_0 \quad (4)$$

Where  $c = CMOD/P$  is the compliance of specimens,  $b$  is specimens thickness;  $h$  is specimens height and  $h_0$  is the thickness of the clip gauge holder. For calculation of critical value of equivalent-elastic crack length  $a_c$ , the value of crack mouth opening displacement ( $CMOD$ ) and  $P$  is taken as  $CMOD_c$  and  $P_u$  respectively.

The residual Young's modulus  $E$  is calculated using the  $P$ - $CMOD$  curve as:

$$E = \frac{1}{bc_i} [13.18 \times (1 - \alpha)^2 - 9.16] \quad (5)$$

Where  $c_i = CMOD_{ini}/P_{ini}$ , is the initial compliance before cracking,  $\alpha = (a_0 + h_0)/(h + h_0)$ . The value of critical equivalent-elastic crack length  $a_c$  and residual Young's modulus  $E$  are listed in Table 2.

### 3.2 Crack opening displacement along the fracture process zone

Since the cohesive stress distribution along the fracture process zone depends on the crack opening displacement and the specified softening law, it is important to know the value of crack opening displacement along the fracture line. It is difficult to measure directly the value of  $COD$  along the fracture process zone, for practical purposes the value of  $COD(x)$  at the crack length  $x$  is computed using the following expression [3]:

$$COD(x) = CMOD \left\{ \left( 1 - \frac{x}{a} \right)^2 + (1.018 - 1.149 \frac{a}{h}) \left[ \frac{x}{a} - \left( \frac{x}{a} \right)^2 \right] \right\}^{1/2} \quad (6)$$

For calculation of critical value of crack tip opening displacement  $CTOD_c$ , the value of  $x$  and  $a$  (see in Fig.4) in Eq. (6) is taken to be  $a_0$  and  $a_c$ , respectively. The value of cohesive stress along the fictitious fracture zone to the corresponding crack opening displacement is evaluated using bilinear stress-displacement softening law as given in Eq. 3.

### 3.3 Determination of stress intensity factor caused by cohesive force

The standard Green's function [27] for the edge cracks with finite width of plate subjected to a pair of normal forces is used to evaluate the value of cohesive toughness. The general expression for the crack extension resistance for complete fracture associated with cohesive stress distribution in the fictitious fracture zone for Mode I fracture is given as below:

$$K_I^c = \int_{a_0}^a 2\sigma(x) F\left(\frac{x}{a}, \frac{a}{h}\right) / \sqrt{\pi a} dx \quad (7)$$

Where

$$F\left(\frac{x}{a}, \frac{a}{h}\right) = \frac{3.52(1-x/a)}{(1-a/h)^{3/2}} - \frac{4.35-5.28x/a}{(1-a/h)} + \left\{ \frac{1.30-0.30(x/a)^{3/2}}{\sqrt{1-(x/a)^2}} + 0.83-1.76\frac{x}{a} \right\} \left\{ 1 - \left(1 - \frac{x}{a}\right) \frac{a}{h} \right\} \quad (8)$$

and  $\sigma(x)$  is the cohesive force at crack length  $x$ , see in Fig.3, its expression is shown in Eqs.9 or 11. At critical condition the value of  $a$  is taken to be  $a_c$  in Eqs.7 and 8. The integration of the Eq.8 is done by using Gauss-Chebyshev quadrature method because of existence of singularity at the integral boundary.

As shown in Fig.2, two conditions at critical load, i.e.,  $CTOD_c \leq w_s$  and  $w_s \leq CTOD_c \leq w_c$  may arise at the notch-tip while using bilinear softening function. For specimens subjected to temperatures less than 120°C, the critical  $CTOD_c$  is less than  $w_s$ ; whereas, for temperatures higher than 120°C, the critical  $CTOD_c$  is wider than  $w_s$ .

Fig.2. Two different situations for  $CTOD_c$  and  $w_s$

(a) The linear distribution of cohesive force

(b) The bilinear distribution of cohesive force

Fig.3. Cohesive force distribution along the crack length at critical load

**A.** When the critical  $CTOD_c$  corresponding to maximum load  $P_u$  is less than  $w_s$  as shown Fig.2a. The distribution of cohesive stress along the fictitious fracture zone is approximated to be linear as shown in Fig.3a. The variation of cohesive stress along the fictitious fracture zone for this loading condition i.e.,  $a_0 \leq a \leq a_c$  or  $0 \leq CTOD \leq CTOD_c$  is written as:

$$\sigma(x) = \sigma(CTOD_c) + (f_t - \sigma(CTOD_c))(x - a_0)/(a_c - a_0) \quad (9)$$

where,  $\sigma(CTOD_c)$  is the critical values of cohesive stress being at the tip of initial notch. The value of  $\sigma(CTOD_c)$  is determined by using bilinear softening function:

$$\sigma(CTOD_c) = \sigma_s(w_s) + \frac{w_s - CTOD_c}{w_s} (f_t - \sigma_s(w_s)) \quad (10)$$

**B.** When the critical  $CTOD_c$  corresponding to maximum load  $P_u$  is wider than  $w_s$  as shown Fig.2b. The distribution of cohesive stress along the fictitious fracture zone is approximated to be bilinear as shown in Fig.3b. The variation of cohesive stress along the fictitious fracture zone for this loading condition, also,  $a_0 \leq a \leq a_c$  or  $0 \leq CTOD \leq CTOD_c$  is written as:

$$\begin{cases} \sigma_1(x) = \sigma(CTOD_c) + (\sigma_s(w_s) - \sigma(w)) \frac{(x - a_0)}{(a_s - a_0)} & a_s \leq x \leq a_0 \\ \sigma_2(x) = \sigma_s(w_s) + (f_t - \sigma_s(w_s)) \frac{(x - a_s)}{(a_c - a_s)} & a_s \leq x \leq a_c \end{cases} \quad (11)$$

The value of  $\sigma(CTOD_c)$  is determined by using bilinear softening function:

$$\sigma(CTOD_c) = \frac{w_0 - CTOD_c}{w_0 - w_s} \sigma_s(w_s) \quad (12)$$

The limits of integration of Eq.7 should be taken in two steps:  $a_0 \leq x \leq a_s$  for cohesive stress  $\sigma_1(x)$  and  $a_s \leq x \leq a_c$  for cohesive stress  $\sigma_2(x)$  respectively. The same Green's function  $F(x/a, a/h)$  for a given effective crack extension will be determined using Eq.8. The calculated formula is listed as follows:

$$K_I^c = \int_{a_0}^{a_s} 2\sigma_1(x)F\left(\frac{x}{a_c}, \frac{a_c}{h}\right)/\sqrt{\pi a_c} dx + \int_{a_s}^{a_c} 2\sigma_2(x)F\left(\frac{x}{a_c}, \frac{a_c}{h}\right)/\sqrt{\pi a_c} dx \quad (13)$$

The effective crack length at break point  $a_s$  (shown in Fig.3b), is computed from the following nonlinear expression<sup>[24]</sup> by substituting  $COD(a_s)$ ,  $CMOD$ ,  $a_c$  and  $h$ :

$$COD(a_s) = CMOD \left\{ \left(1 - \frac{a_s}{a_c}\right)^2 + (1.018 - 1.149 \frac{a_c}{h}) \left[ \frac{a_s}{a_c} - \left(\frac{a_s}{a_c}\right)^2 \right] \right\}^{1/2} \quad (14)$$

Where  $COD(a_s)$  is the crack opening displacement at  $a_s$ ,  $a_c$  is the effective crack length (according to Eq.4) and  $h$  is the specimen height.

## 4. Proposed method to determine cohesive fracture toughness using weight function

### 4.1. Introduction of weight function

Use of weight functions for calculation of stress intensity factors provides an efficient analytical technique for fracture mechanics applications. The method of weight function was initially proposed by Bueckner [28] and Rice [29] for determination of stress intensity factors and crack face displacements in cracked bodies under arbitrary applied stress fields. The value of cohesive fracture toughness  $K_s$  may be directly determined using weight function as below:

$$K_S = \int_0^a \sigma_s(x) m(x, a) dx_s \quad (15)$$

The term  $m(x, a)$  in Eq.15 is known as weight function and expressed as:

$$m(x, a) = \frac{E'}{2K_r} \frac{\partial u_r}{\partial a} \quad (16)$$

where,  $a$  = crack length;  $\sigma_s(x)$  = the stress distribution along the crack line in the uncracked body under the loading case  $s$ , which can be determined either experimentally or numerically or analytically;  $dx_s$  = the infinitesimal length along the crack surface;  $E' = E$  for plane stress and  $E' = E/(1 - \nu^2)$  for plane strain,  $E$  and  $\nu$  are the Young's modulus and the Poisson's ratio respectively.

### 4.2. Determination of universal weight function for an edge crack in finite width plate

Several one-dimensional weight functions with various mathematical forms are available in literature [31-33] but their use is limited. Glinka and Shen [34] introduced one universal form of weight function expression having four terms, which can be used for variety of one-dimensional Mode I crack problems:

$$m(x, a) = \frac{2}{\sqrt{2\pi(a-x)}} [1 + M_1(1 - \frac{x}{a})^{1/2} + M_2(1 - \frac{x}{a}) + M_3(1 - \frac{x}{a})^{3/2}] \quad (17)$$

$$\text{For } i=1, 3 \quad M_i = \frac{1}{\sqrt{(1-a/D)^3}} [a_i + b_i a/D + c_i (a/D)^2 + d_i (a/D)^3 + e_i (a/D)^4 + f_i (a/D)^5] \quad (18)$$

$$\text{For } i=2 \quad M_i = [a_i + b_i a/D] \quad (19)$$

The values of coefficients  $a_i, b_i, c_i, d_i, e_i, f_i$  are given in Table 1. For an edge crack in the finite width of plate the accuracy of the weight function are verified with respect to Tada et al. [27] Green's function.

Table 1 Coefficients of four terms weight function parameters  $M_1, M_2$  and  $M_3$

$i$	$a_i$	$b_i$	$c_i$	$d_i$	$e_i$	$f_i$
1	0.0572	-0.8742	4.0466	-7.8994	7.8550	-3.1883
2	0.4935	4.4365				
3	0.3404	-3.9534	16.1904	-16.0959	14.6302	-6.1307

### 4.3. Evaluation of cohesive fracture toughness

Once the weight function parameters are determined, Eq.15 is used to calculate the stress intensity factor at critical condition due to cohesive stress distribution as shown in Fig.3. The value of  $\sigma(x)$  in Eq.15 is replaced by Eq.10, Eq.11, hence the closed form expression of  $K_I^c$  is can be obtained. The value of  $K_I^c$  using four terms weight function is expressed in the following form.

**A.** When the critical  $CTOD_c$  corresponding to maximum load  $P_u$  is less than  $w_s$  as shown Fig.2a:

$$K_I^c = \int_0^{a_c} \left\{ \sigma(CTOD_c) + (f_i - \sigma(CTOD_c))(x - a_0)/(a_c - a_0) \right\} \times \frac{2}{\sqrt{2\pi(a_c - x)}} [1 + M_1(1 - \frac{x}{a_c})^{1/2} + M_2(1 - \frac{x}{a_c}) + M_3(1 - \frac{x}{a_c})^{3/2}] dx_s \quad (20)$$

After integration of Eq.20 the closed form solution of  $K_I^c$  is determined as:

$$K_{Ic} = \frac{2}{\sqrt{2\pi a_c}} (A_1 B_1 a_c + A_2 B_2 a_c^2) \quad (21)$$

Where  $A_1 = \sigma(CTOD_c)$ ,  $A_2 = \frac{f_i - \sigma(CTOD_c)}{a_c - a_0}$ ,  $S = (1 - a_0/a_c)$ ,

$$B_1 = 2S^{1/2} + M_1 S + 2/3 M_2 S^{3/2} + M_3 S^2/2, \quad B_2 = 4/3 S^{3/2} + M_1 S^2/2 + 4/15 M_2 S^{5/2} + M_3 S^3/6.$$

**B.** When the critical  $CTOD_c$  corresponding to maximum load  $P_u$  is wider than  $w_s$  as shown Fig.2b.

$$K_I^c = \int_0^{a_c} \left\{ \sigma(CTOD_c) + (\sigma_s(w_s) - \sigma(w)) \frac{(x - a_0)}{(a_s - a_0)} + \sigma_s(w_s) + (f_i - \sigma_s(w_s)) \frac{(x - a_s)}{(a_c - a_s)} \right\} \times \frac{2}{\sqrt{2\pi(a_c - x)}} [1 + M_1(1 - \frac{x}{a_c})^{1/2} + M_2(1 - \frac{x}{a_c}) + M_3(1 - \frac{x}{a_c})^{3/2}] dx_s \quad (22)$$

After integration of Eq.22 the closed form solution of  $K_I^c$  is determined as:

$$K_I^c = \frac{2}{\sqrt{2\pi a_c}} \{A_1 a_c [B_1 - B_3] + A_3 a_c^2 [B_1 - B_3 - B_4 + B_5]\} - \frac{2}{\sqrt{2\pi a_c}} \{A_3 a_c a_0 [B_1 - B_3]\} + \frac{2}{\sqrt{2\pi a_c}} \{A_4 B_3 a_c + A_5 B_3 a_c^2\} - \frac{2}{\sqrt{2\pi a_c}} \{A_5 a_c a_s B_3\} + \frac{2}{\sqrt{2\pi a_c}} \{A_5 B_5 a_c^2\} \quad (23)$$

Where  $A_1 = \sigma(CTOD_c)$ ,  $A_3 = \frac{\sigma_s(w_s) - \sigma(CTOD_c)}{a_c - a_0}$ ,  $A_4 = \sigma_s(w_s)$ ,  $A_5 = \frac{f_t - \sigma_s(w_s)}{a_c - a_0}$ ,  
 $B_1 = 2S_1^{1/2} + M_1S_1 + 2/3M_2S_1^{3/2} + M_3S_1^2/2$ ,  $B_3 = 2S_2^{1/2} + M_1S_2 + 2/3M_2S_2^{3/2} + M_3S_2^2/2$ ,  
 $B_4 = 2/3S_1^{1/2} + M_1S_1^2/2 + 2/5M_2S_1^{5/2} + M_3S_1^3/3$ ,  $B_5 = 2/3S_2^{3/2} + M_1S_2^2/2 + 2/5M_2S_2^{5/2} + M_3S_2^3/3$ ,  
 $S_1 = (1 - a_0/a_c)$ ,  $S_2 = (1 - a_s/a_c)$ .

## 5 Calculation of double-K fracture parameters

The two parameters ( $K_I^{ini}$  and  $K_I^{un}$ ) of double-K fracture criterion for wedge-splitting test is determined using linear elastic fracture mechanics formula given in XU[8]:

$$K(P, a) = \frac{P \times 10^{-3}}{th^{1/2}} f(\alpha) \quad (24)$$

$$f(\alpha) = \frac{3.675 \times [1 - 0.12(\alpha - 0.45)]}{(1 - \alpha)^{3/2}}, \alpha = \frac{a}{h} \quad (25)$$

The empirical expression (24) is valid within 2% accuracy for,  $0.2 \leq \alpha \leq 0.8$ .

Equations 24 and 25 can be used in calculation of unstable fracture toughness,  $K_I^{un}$  at the tip of effective crack length  $a_c$ , in which  $a = a_c$  and  $P =$  maximum load,  $P_u$  for TPBT and CT test specimen geometries respectively. The initiation toughness,  $K_I^{ini}$  is calculated using Eqs.24 and 25 when the initial cracking load,  $P_{ini}$  at initial crack tip is known. In present paper, the  $P_{ini}$  is determined by graphical method using the starting point of non-linearity in  $P$ - $CMOD$  curve described in the following section.

Generally, for post-fire concrete specimens the value of initial fracture toughness  $K_I^{ini}$  is far less than the value of critical fracture toughness  $K_I^{un}$ , especially for higher temperatures. So much more consideration is put to the critical fracture toughness  $K_I^{un}$ . In double-K fracture model, the following relation can be employed:

$$K_I^{un} = K_I^{ini} + K_I^c \quad (26)$$

Since there are two methods to determine the cohesive fracture toughness as mentioned above. Here we donate the experimental value, analytical value and weight function value of critical fracture toughness as  $K_I^{un-e}$ ,  $K_I^{un-A}$ ,  $K_I^{un-W}$  respectively, and from which we would judge the validation of double-K fracture model and weight function method to the post-fire concrete.

## 6. Experimental validation and comparison of results

### 6.1. Experimental program and experimental phenomena

To obtain the complete  $P$ - $CMOD$  curves, the wedge-splitting tests were implemented. A total of 50 concrete specimens with the same dimensions  $230 \times 200 \times 200$  mm were prepared, the geometry of the specimens is shown in Fig.4 ( $b=200$ mm,  $d=65$ mm,  $h=200$ mm,  $f=30$ mm,  $a_0=80$ mm,  $\theta=15^\circ$ ). The concrete mix ratios (by weight) were Cement: Sand: Coarse aggregate: Water = 1.00:3.44:4.39:0.80, with common Portland cement-mixed medium sand and 16-mm graded coarse aggregate. All the specimens had a precast notch of 80 mm height and 3 mm thickness, achieved by placing a piece of steel plate into the molds prior to casting. Each wedge splitting specimen was embedded with a thermal couple in the center of specimen for temperature control.

Nine heating temperatures, ranging from  $65^\circ\text{C}$  to  $600^\circ\text{C}$  ( $T_m=65^\circ\text{C}$ ,  $120^\circ\text{C}$ ,  $200^\circ\text{C}$ ,  $300^\circ\text{C}$ ,  $350^\circ\text{C}$ ,

400°C, 450°C, 500°C, 600°C), were adopted with the ambient temperature as a reference. Because it was recognized that the fracture behavior measurements were generally associated with significant scatter, five repetitions were performed for each temperature.

A closed-loop servo controlled hydraulic jack with a maximum capacity of 1000 kN was employed to conduct the wedge splitting tests (shown in Fig.5). Two Clip-on Extensometers were suited at the mouth and the tip of the crack to measure the crack mouth opening displacement (*CMOD*) and crack tip opening displacement (*CTOD*). To obtain the complete *P-CMOD* curves (shown in Fig.6), the test rate was fixed at 0.4 mm/min.

Fig. 4. The geometry of specimens

Fig. 5. The experiment set-up

For the specimens exposed to relatively lower temperatures (20°C~200°C), the splitting load generally reached its peak with no visible crack observed. Once the first crack initiated, the splitting load dropped dramatically. For temperatures at 20°C~200°C shows that the crack propagated vertically to the bottom of the specimen along with the precast notch. At temperatures above 200°C, more than one crack branched from the tip of notch, competing to form the final fracture (shown in Fig.7).

Fig.6. *P* vs *CMOD* curves of specimens with temperatures Fig. 7. Testing phenomenon of post-fire specimens

## 6.2. Experimental results

Fig.6 shows typical complete load-displacement curves for different heating temperatures up to 600°C. The figure shows that the ultimate load  $P_u$  decreases significantly with increasing temperatures  $T_m$ , whereas the crack-mouth opening displacement (*CMOD*) increases with  $T_m$ . The initial slope of ascending branches decrease with heating temperatures, and the curves become gradually shorter and more extended.

The recorded maximum load  $P_u$ , the recorded crack mouth opening displacement  $CMOD_c$  at  $P_u$ , the calculated crack tip opening displacement  $CTOD_c$  based on Eq.14, the initial cracking load  $P_{ini}$  determined by graphical method, the calculated residual Young's modulus  $E$  based on Eq.5, the

double-K fracture parameters, i.e.,  $K_I^{ini}$  and  $K_I^{un-E}$  and the residual fracture energy  $G_F$  are summarized in Table 2. Here we only list part of the statistics.

Table 2 The experimental results of fracture parameters

specimen	temperature	$P_{ini}/$ kN	$P_{max}/$ kN	$CMOD_c$ /mm	$CTOD_c$ /mm	$E$ GPa	$G_F$ N/m	$K_I^{ini}$ MPa m <sup>1/2</sup>	$K_I^{c-A}$ MPa m <sup>1/2</sup>	$K_I^{c-W}$ MPa m <sup>1/2</sup>	$K_I^{un-E}$ MPa m <sup>1/2</sup>	$K_I^{un-A}$ MPa m <sup>1/2</sup>	$K_I^{un-W}$ MPa m <sup>1/2</sup>

### 6.3. Discussion

In order to express the influence on the residual fracture toughness in detail, Fig.8 plots the tendency of initial fracture toughness  $K_I^{ini}$  and the unstable fracture toughness  $K_I^{un}$  with heating temperatures  $T_m$ . It is concluded that the two fractures toughness decrease monotonously with  $T_m$  because of the thermal damage induced by the heating temperatures.

The initial fracture toughness continuously decreases from 0.498 kN at room temperature to 0.269 kN at 200°C, 0.115 kN at 450°C, and finally 0.064kN at 600°C, with a significant loss of 0.434 kN or 96%. The unstable fracture toughness decreases from 1.186 kN at room temperature to 0.297 at 600°C, with a significant loss of 0.889 kN or 75%.

(a) The tendency of  $K_I^{ini}$  with  $T_m$

(b) The tendency of  $K_I^{un}$  with  $T_m$

Fig.8. The tendency of residual fracture toughness with heating temperatures  $T_m$

Comparing the result shown in Table 2, it can be known that the value of  $K_I^{un-A}$  evaluated by formula (26) has a good coincidence to one calculated by inserting the values of  $P_{max}$  and  $a_c=D$  into the formula (24), i.e. the critical fracture toughness from analytical and experimental method. Fig.9 shows the relationship between the two parameters. The similar results could be concluded between the value of  $K_I^{un-W}$  from formula (26) and the experimental results from formula(24).

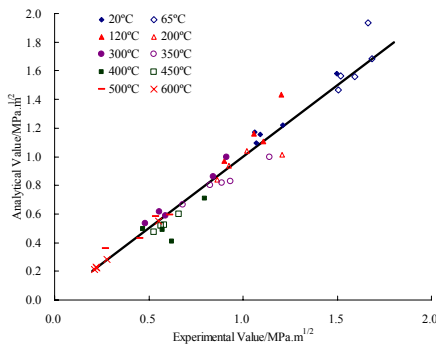

Fig.9. Comparison between analytical and experimental values of critical fracture toughness

Fig.10. Comparison between analytical and weight function values of critical fracture toughness

In totally 45 effective specimens, the deviation between  $K_I^{un-A}$  and  $K_I^{un-E}$  of 22 specimens is below 5%, and of 40 specimens is below 15%, account for 89% of total specimens. Accordingly, the number of specimens corresponding to the same deviation between  $K_I^{un-W}$  and  $K_I^{un-E}$  is 20 and 42, respectively.

Fig.10 shows the weight function method agrees well with the analytical method, and the deviation below 5% accounts for 65% of total specimens.

## 7. Conclusion

The determination of double-K fracture parameter using both analytical and weight function methods are carried out in present research. In calculating the cohesive fracture toughness, two conditions are divided at critical load: for specimens subjected to temperatures less than 120°C, the critical  $CTOD_c$  is less than  $w_s$ ; whereas, for temperatures higher than 120°C, the critical  $CTOD_c$  corresponding to maximum load  $P_u$  is wider than  $w_s$ . This part of work would be a useful supplement to the existed analysis.

Wedge-splitting tests with ten temperatures varying from 20°C to 600°C are implemented. The complete load-crack opening displacement curves are obtained and the initial and critical fracture toughness could be calculated experimentally.

The validation of double-K fracture model to the post-fire concrete specimens is proved. In totally 45 effective specimens, the deviation between analytical value  $K_I^{un-A}$  and experimental  $K_I^{un-E}$  of 22 specimens is below 5%, and of 40 specimens is below 15%, account for 89% of total specimens. Accordingly, the number of specimens corresponding to the same deviation between  $K_I^{un-W}$  and  $K_I^{un-E}$  is 20 and 42, respectively. Meanwhile the weight function method agrees well with the analytical method, and the deviation below 5% accounts for 65% of total specimens.
